Key Points

**Magnetic Resonance Imaging**
- MRI is an effective diagnostic tool to assess damage to microstructures within the spinal cord as well as detecting other indications of damage such as hemorrhage and edemas.
- MRI may be reliably used to predict an individual’s injury severity, American Spinal Injury Association score, motor score, AIS, and neurologic outcome given an SCI.
- For individuals with SCI without radiographic abnormality MRI may not be useful in determining current injury severity or predicting outcome following injury.

**Diffusion Tensor Imaging**
- DTI has value as a diagnostic imaging tool to evaluate microstructural and spinal cord abnormalities in individuals with SCI.
- There is conflicting evidence as to which observations from DTI can be used to predict current and future outcomes.
- DTI may be effective for predicting relationships between different SCI abnormalities within individuals.

1.0 Executive Summary

Overall studies using magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) provide strong evidence that these are important imaging tools in the diagnosis, prognosis, and evaluation of injuries associated with SCI. MRI was shown to have high sensitivity and specificity in the detection of microstructural abnormalities related to SCI, and that these observations can be used to predict motor score and classification. There is limited evidence to suggest that MRI may be useful in the diagnosis and prognosis of motor classification in individuals with SCI without radiographic abnormalities. With respect to DTI, there is strong evidence to support its use as a diagnostic tool, however the evidence surrounding its use as a prognostic indicator are mixed. In general, there are fewer studies reporting the use of DTI in relation to SCI management compared to the use of MRI.

2.0 Methods

A key word literature search for scientific articles published between January 1, 2015 to August 31, 2018 investigating the use of imaging tools in the diagnosis and management of SCI was conducted using the following online databases: MEDLINE, CINAHL, Scopus, EMBASE and Cochrane Library. Population key words (i.e., spinal cord injury, quadriplegia, hemiplegia, and tetraplegia) and imaging key words (i.e., magnetic resonance imaging, CT, computed tomography, radiograph, x-ray, and imaging) were used. The search was limited to journal articles, reviews, or systematic reviews (excluding case reports) which were published in English, had a minimum sample of three adults (≥18 years) with an SCI. The SCI population within each study must have comprised of at least 50% of the total study population, unless results were stratified. A total of 4762 studies were found that satisfied the search criteria, after the removal of duplicates, animal and pediatric studies, and case reports 34 studies remained. Studies were considered appropriate for inclusion in this chapter if the majority of participants were within 3 months post-SCI. Articles were then further subdivided into groups based on the imaging technique used.

3.0 Introduction

Imaging plays a critical role in the diagnosis, treatment and rehabilitation of individuals with SCI. Conventional imaging tools have provided anatomical information leading to more targeted and overall better management of these individuals no doubt, but more recent development of advanced imaging techniques are capable of providing microstructural and metabolic information as well. Conventional radiography and computed tomography (CT) give macrostructural information about bony structures mainly, critical for the vertebral column. Comparison of different imaging modalities helps understand appropriate use, risks and benefits of each, financial aspects and radiation issues involved, all leading to avoidance of unnecessary delay in more advanced care or treatment.
Prognosis of SCI is discussed in brief. Moreover, the psychometrics of MRI related to sensitivity, specificity, and interrater reliability are explored. More modern techniques capable of providing microstructural information built mostly upon these basic anatomic imaging tools are now available in many places and in a short subsection we discuss DTI and its role in identifying SCIs. Many more modern techniques, such as spectroscopy and perfusion MRI, are used in the research domain and are not currently being used in clinical practice, therefore, are not evaluated here. The following chapter will review contemporary clinical roles of non-invasive imaging pertaining to spinal cord injury, as well as, their role, prognostic and diagnostic.

4.0 Radiography and Computed Tomography (CT)

Plain radiographs use x-rays to create an image of the body using various projections (frontal, lateral). Plain radiographs play a rather limited role in today’s assessment protocols for SCI, but nevertheless retain value as a quick screening tool in many situations and also are a quick way of assessing instability of the vertebral column with flexion, neutral position and extension views easily obtainable. CT is the best modality for assessment of bony details but remains rather limited for cord assessment. CT is a modality that uses x-rays to create cross-sectional images or slices of the body.

5.0 Magnetic Resonance Imaging (MRI)

MRI is an imaging modality that uses non-ionising radiation to construct useful diagnostic images. MRI with superior soft tissue resolution gives critical information on ligamentous, soft tissue and cord injury and is currently the gold standard for soft tissue assessment. Here in this chapter, we discuss MRI for assessment of traumatic SCI. MRI is the imaging modality of choice to diagnose acute cord compression and its effects in SCI.

Case Control  
N=47 | **Population:** SCI (n=24): Mean age=49.7±19.8yr; Gender: males=19, females=5; Level of injury: C=12, T=9, L=2, S=1; Mean time since injury=45.6±20.7d; AIS scale: A=6, B=5, C=4, D=9. Healthy controls (n=23): Mean age=35.9±10.9yr; Gender: males=13, females=10; Level of injury: N/A; Time since injury=N/A; AIS scale: N/A.  
**Intervention:** All participants underwent magnetic resonance imaging (MRI) using a 3T system. Sequences included T1-weighted 3D magnetization Prepared Rapid Acquisition Gradient-Echo (IMPRA)GE of the whole brain extending to the cervical C5 level (field of view=224 X 256, matrix=224 X 256, repetition time/echo (TR/TE)=2420/4.18 ms, bandwidth=150 hz/pixel). Microstructural changes were assessed with three different 3D multi-echo fast low-angle shot (FLASH) gradient-echo sequences. | | | 1. The mean±SD for intra-observer ICC was 0.88±0.1 for MCC, 0.76±0.08 for MSCC, 0.92±0.07 for TA, and 0.82±0.13 for CR.  
2. Additionally, inter-observer ICC was 0.75±0.04 for MCC, 0.79±0.09 for MSCC, 0.80±0.05 for CR, and 0.86±0.03 for TA.  
3. SCA (p=0.004) and APW (p=0.005) were significantly lower compared to controls at baseline. There was no significant difference in LRW between the two groups at baseline (p=0.67).  
4. There were no significant differences in microstructural measures of MT, R1, and R2 in the cervical cord when comparing SCI to controls (p>0.05). |
Participants were assessed at baseline, 2, 6, 12, and 24 mo post-SCI. **Outcome Measures**: Cross-sectional spinal cord area (SCA); anterior-posterior width (APW); left-right width (LRW); lower extremity motor score (LEM); Microstructural parameters: magnetization transfer (MT); longitudinal relaxation rate (R1); effective transverse relaxation rate (R2).

### Dalkilic et al., (2018)

**Population**: SCI (n=36): Mean age=42.1±13yr; Gender: males=23, females=13; Level of injury: C=36; Mean time since injury=12.87hr; AIS: A=20, B=7, C=9.

**Intervention**: Individuals were assessed using magnetic resonance imaging (MRI) pre-operatively with a 1.5T MRI system. Conventional MRI sequences included were fast-spin-echo (FSE) T1-weighted sagittal image with repetition time/echo time (TR/TE) =533/10ms, T2-weighted sagittal image with TR/TE=3000/84ms, FSE T2-weighted axial image with TR/TE=3390/98ms, and T2 gradient echo weighted axial image with TR/TE=1030/24ms. AIS grade was assessed pre-operatively (baseline) and 6mo post-injury. Outcome measures below were assessed by MRI. **Outcome Measures**: Intramedullary lesion length (IMLL); hematoma length; CSF effacement length; cord expansion length; maximal cord compression (MCC).

1. Hematoma length (p=0.006), CSF effacement length (p=0.007), and cord expansion length (p=0.031) differed significantly between individuals with baseline AIS grades A, B, and C. There were no significant differences in IMLL and MCC (p>0.05).
2. A logistic regression model of MRI found that only CSF effacement and hematoma length were statistically significant predictors of baseline AIS grade (p<0.05). The model had 72.2% accuracy for AIS grade classification.
3. IMLL (p=0.031) and hematoma length (p=0.002) were significantly higher in individuals who converted their AIS grade within 6mo compared to those who did not. CSF effacement, cord expansion length, and MCC did not differ significantly between the two groups (p>0.05).

### Aarabi et al., (2017)

**Population**: SCI (n=100): Mean age=39.5±16.8yr; Gender: males=89, females=11; Level of injury: C=100; Time since injury: ≤12hr=51, >12hr=49; AIS: A=52, B=29, C=19.

**Intervention**: Individuals who underwent surgical spinal cord decompression were included in this longitudinal, retrospective study. AIS grade was re-evaluated at 6wk, 3mo, 6mo, and 12mo following discharge. Post-operative magnetic resonance imaging (MRI) was used to assess outcome measures. Outcome measures below were assessed by MRI. **Outcome Measures**: AIS grade conversion at 6mo post-surgery; Intramedullary lesion length (IMLL); evidence of decompression; presence of intramedullary hematomas.

1. IMLL was a significant predictor of AIS impairment scale grade conversion at 6mo in univariate (p<0.001) and sole predictor in multivariate (OR=0.950, CI: 0.931-0.969) analysis. The multivariate model predicted 5% and 40% decreases in the odds of AIS scale grade conversion for 1- and 10mm increases in IMLL, respectively.
2. Univariate analysis showed that the presence of intramedullary and evidence of decompression were significantly related to AIS grade conversion at 6mo (p<0.001), however, were not significant in multivariate analysis (stepwise multiple logistic regression) (p>0.05).

- Injury: 6 (range: 5-11) d; AIS scale: B=3, C=7, D=2. **Intervention:** Participants with closed cervical SCI were recruited for this prospective study. MRI was performed on all participants. Neurological impairment was assessed at time of MRI and at median follow up of 35 mo (range=24-65). **Outcome Measures:** hemorrhage length; edema length; American Spinal Injury Association (ASIA) classification; recovery rate (RR) of the following: motor score; sensory score; pin prick score. | **3.** Baseline motor, pin prick, and sensory scores were significantly lower in the presence of hemorrhage (p=0.006; p=0.001; p=0.001, respectively). **4.** RR of pin prick and sensory scores were significantly lower in participants with hemorrhage (p=0.008; p=0.011, respectively). There was no significant difference in RR of motor score between hemorrhage versus no hemorrhage (p>0.05). **5.** ANOVA revealed statistically different edema lengths among the levels of ASIA score (p=0.001). ASIA A was statistically longer than ASIA C, D, and E. There was no difference in edema length when comparing ASIA A to B (p>0.05). **6.** Hemorrhage length was longer in complete SCI (ASIA A) compared to incomplete SCI (ASIA B-E) (p=0.002). **7.** Logistics regression revealed that length of edema was the only predictive measure for all participants (hemorrhage and no hemorrhage). Each mm increase in edema resulted in a 1.15 (1.03-1.29) increased rate of retaining a complete SCI (p=0.022). |

**Population:** *Cervical Myelopathy (n=55):* Mean age: 29.2yr; Gender: males=36, females=19; Injury etiology: motor vehicle accident=32, diving accident=11, fall=9, other=3; Level of injury range: C2-T1; Level of severity: Frankel grade A=32, B=9, C=8, D=6; Time since injury range: <17hr.

**Intervention:** Individuals with traumatic cervical myelopathy underwent magnetic resonance imaging (MRI) of the spine. Outcomes were assessed at admission and at the most recent follow-up visit an average of 18.5mo.

**Outcome Measures:** Frankel Grade, Medical Research Council (MRC) motor grades, Spinal cord length and diameter, Presence of hematoma, edema, and hemorrhage.

5. A logistic regression adjusting for neurological examination scores at baseline found that there were no significant increased odds for a complete spinal cord injury in the presence of hemorrhage, contusion or edema (p>0.05).

8. There was no significant difference in motor function and sensory recovery at 6wk when comparing participants with hemorrhage, contusion, and edema (p>0.05).

1. Abnormal T2-hyperintensity MRI images representing edema were present in 54 of 55 individuals.

2. Rostrocaudal length of signal changes, but not spinal cord swelling or maximal diameter, was significantly correlated with poor neurological function on Frankel Grades at admission (p=0.001).

3. Abnormal T2-hypointensity representing intra-axial hemorrhage was present in 22 individuals (40%), all which had poor Frankel Grade A or B injuries on admission and this was significantly different than those without hypointense signals (p=0.001).

4. Rostrocaudal length of hemorrhage signal changes were significantly correlated with worse Frankel Grades after MRI (p=0.049), but not at follow-up.

5. Rostrocaudal length of edema, but not maximal diameter or length, was significantly correlated with worse Frankel Grade at the follow-up (p=0.036).

6. The strongest predictor of neurological outcome was Frankel Grade at presentation (p<0.001).

7. Hemorrhage on MRI scans were correlated with motor-complete injury at admission and associated with poor long term Frankel Grade scores.

8. There was a decrease in Frankel Grade at admission to follow-up for rostrocaudal length of hematoma (p=0.028), compression via extra-axial hematoma (p=0.077) and rostrocaudal length of edema (p=0.071).

9. There was a significant negative correlation between length of spinal edema on MRI and total motor score improvements on MRC (p=0.041).

**Discussion**

MRI is the imaging modality of choice in SCI due to its high psychometric and prognostic value. Yasin et al., show that MRI is a highly sensitive (97%) and accurate technique (95%). MRI demonstrated high psychometrics in SCI with or without edema and hemorrhage, except when trying to assess for combination of edema and hemorrhage without contrast as Ghasemi et al., (2015) demonstrate. Karpova et al., (2013) demonstrate high intraobserver correlation for quantitative MRI measurements related to the spine.

MRI also showed strong prognostic value in predicting the initial injury and course of injury based on signal intensity. Selden et al., (1999) showed that hemorrhage on MRI scans were correlated with motor-complete injury at admission and associated with poor long-term Frankel Grade scores. Initial MRI pattern was associated with recovery. MRI signal characteristics consistent with spinal cord edema or hemorrhage predicted worse functional outcome as Wilson et al., demonstrate. The study conducted by Flanders et al., (1996) found that individuals with spinal cord hemorrhage had significantly worse upper and lower motor scores at the time of injury and at 12 months. Miyanji et al., (2007) demonstrate that the frequency of intramedullary hemorrhage, edema, and cord swelling were more common in American Spinal Injury Association A versus American Spinal Injury Association B-D. Moreover, they were directly correlated with SCI severity. Only one study by Wang et al., (2016) showed no significant correlation between MRI findings and motor, sensory or American Spinal Injury Association score.
Conclusion

There is level 4 evidence (from one case series study; (Karpova et al., 2013), and two observational studies; (Ghasemi et al., 2015, Yasin et al., 2017) that MRI has strong inter-observer correlation, sensitivity, specificity, predictive value, and diagnostic accuracy in detecting and evaluating SCI in individuals.

There is level 5 evidence (from one case series study; (Schroeder et al., 2016) that the incidence of surgical treatment and spinal decompression is not significantly different between individuals based on the presence of signal intensity on an MRI.

There is conflicting level 3 evidence (from one cohort study; (Mabray et al., 2016), one case control study; (Seif et al., 2018), two case series; (Flanders et al., 1996), (Wilson et al., 2012), and six observational studies; (Arabi et al., 2017, Schaefer et al., 1992, Selden et al., 1999, Song et al., 2016, Takahashi et al., 1993, Zohrabian et al., 2016) and level 5 evidence (from one observational study (Wang et al., 2016) that MRI is effective in determining microstructural measurements and can reliably predict AIS classification, motor score and status and progression of injury in individuals with SCI and controls.

There is level 5 evidence (from one cohort study; (Martinez-Perez et al., 2017) that early MRI has prognostic value in its ability to evaluate ligamentous injury and edema which are predictors of poor neurologic outcome.

There is level 5 evidence (from one observational study; (Miyangi et al., 2007) that MRI can be used to detect hemorrhage, edema, and cord swelling in individuals with SCI. A greater number of positive detections were significantly associated with increased SCI severity and American Spinal Injury Association classification.

There is level 5 evidence (from two observational studies; (Boldin et al., 2006; Shepard & Bracken 1999) that MRI may be used to predict complete SCI given the detection of hemorrhage and edema in individuals with SCI.

There is level 5 evidence (from one observational study; (Dalkilic et al., 2018) that MRI could be used to assess hematoma length and predict AIS classification at baseline.

There is level 5 evidence (from one observational study; (Matsushita et al., 2017) that MRI is effective in detecting spinal microstructures which can be used to effectively predict American Spinal Injury Association motor scores, and Frankel D scores in individuals with SCI.

MRI is an effective diagnostic tool to assess damage to microstructures within the spinal cord as well as detecting other indications of damage such as hemorrhage and edemas.

MRI may be reliably used to predict an individual’s injury severity, American Spinal Injury Association score, motor score, AIS, and neurologic outcome given an SCI.

5.1 Spinal Cord Injury Without Radiographic Abnormality
In some instances, individuals with an SCI may not present with any radiographic abnormalities. Although this is considered less common it is still worth noting. Spinal cord injury without radiological abnormality accounts for approximately 10% of SCIs and can be an indication for MRI. The few studies which have found no radiographic abnormalities are presented in Table 2 below.

</table>

**Intervention:** Individuals who were admitted to hospital with cervical SCI, received MRI imaging within 72 hr, diagnosed with SCIWORA, and had at least 1 yr of follow-up were included in this retrospective study. MRI was performed using a 1.5T magnet with axial T1-weighted images, T2-weighted images, and gradient echo (GRE); and sagittal T1-weighted images, T2-weighted images, and short TI inversion recovery sequences. Neurological status was assessed using the ASIA impairment scale at baseline and 1-yr follow-up. Neurological improvement was defined as the improvement of at least 1 point on the ASIA Impairment Scale. **Outcome Measures:** Disk integrity; swelling; intramedullary hematoma; extramedullary hematoma; edema; cervical canal stenosis; lesion length; maximal canal; maximal spinal cord compromise.

**Intervention:** Individuals diagnosed with SCIWORA were included in this study. T2-weighted sagittal images were acquired using a 1.5T MRI for all individuals. Additionally, individuals underwent a delayed MRI 2 weeks after injury. Outcome measures were assessed at diagnosis and 1-yr follow-up. **Outcome Measures:** Increased signal intensity (ISI) grade and range; prevertebral hyper-intensity range (PVH);
### Discussion

Only two studies meeting our inclusion criteria examined individuals diagnosed with SCI without radiographic abnormality (Martinez-Perez et al., 2017, Ouchida et al., 2016). Martinez-Perez et al., (2017) assessed individuals who had normal CT scans and did not find any significant associations between physiological outcome and neurological improvement, except for in lesion length as seen on MRI. In this case, shorter lesion length was significantly associated with neurological improvement. Ouchida et al., (2016) found that MRI signal intensity was not significantly associated with the Japanese Orthopaedic Association scoring system, but prevertebral hyper-intensity range was. The first study suggests that an early MRI may pick up traumatic lesions in cases where CT has been negative. These studies also loosely suggest that MRI is less useful as a prognostic indicator of outcome and status in individuals diagnosed with SCI without radiographic abnormality compared to those with SCI who demonstrate radiographic abnormalities.

### Conclusions

*There is level 5 evidence (from one observational study; (Martinez-Perez et al., 2017) that an early MRI may have prognostic value in individuals with SCI without CT evidence of trauma.*

*There is level 5 evidence (from an observational study (Ouchida et al., 2016) that MRI may not be an effective diagnostic or prognostic indicator of injury in individuals diagnosed with SCI without radiographic abnormality.*

For individuals with SCI without radiographic abnormality MRI may not be useful in determining current injury severity or predicting outcome following injury.

### 6.0 Diffusion Tensor Imaging (DTI)

DTI is a novel imaging technique, which is an extension of diffusion weighted imaging. It has the potential to identify intact nerve fibre tracts and has been used to image the brain for a variety of conditions. It is currently used mainly as a research tool when imaging the spine and has not been widely implemented in mainstream clinical practice. However, early studies have shown that it holds considerable promise in predicting the severity of spinal cord injury.

single shot echo planar imaging (EPI) sequence (b-value=0,700 s/mm$^2$) using 20 diffusion encoding directions. Images were acquired using Sagittal T1: repetition time/echo time (TR/TE)=450/9.5ms; Sagittal T2:TR/TE=3630/104ms; Axial T1: TR/TE=450/9.6ms and Axial T2: TR/TE=500/15 ms. Images were acquired in the axial plane with an image matrix of 128X128, 5mm slice thickness with no inter-slice gap, and a 280X280mm field of view. SCI participants were reassessed clinically 1-2 mo after imaging.

**Outcome Measures:** Mean diffusivity (MD); fractional anisotropy (FA); Frankel grading system score (FGS).

Shanmuganathan et al., (2017)
USA
Case Control
$N_{\text{initial}}$=45
$N_{\text{final}}$=31

Population: SCI (n=16): Median age=53(range=20-79)yr; Gender: males=13, females=3; Level of injury: C=16; Time since injury=≤5d; The International Standard of Neurological Classification for SCI (ISNCSCI) at discharge: A=5, B=2, C=3, D=6. Healthy Controls (n=15): Median age=46(range=26-69)yr; Gender: males=12, females=3.

Intervention: All participants underwent Diffusion Tensor Imaging (DTI) with a 1.5-T Avanto scanner with a 12-channel head and four-channel neck array using single-shot echo planar imaging (EPI) sequence at a TE/TR of 87/2800 msec. Sagittal T2 (echo time/ repetition time TE/TR)=109/4000 ms), fluid attenuation inversion recovery (FLAIR) (TE/TR=102/8000 msec, echo train length ETL)=13), and axial T2 and T2*, three-dimensional [3D] susceptibility weighted imaging (SWI) (TE/TR=16/30msec, flip angle: 20 degrees) images were included. For SCI, Regions of interest included areas of edema (confirmed by T2 and STIR sequences) and hemorrhage (confirmed by SWI and T2* sequences). For healthy controls, regions of interest included upper (lower brainstem-lower C2), mid (upper C3-lower C5), and lower (upper C6-lower T1) regions. The International Standard of Neurological Classification for SCI (ISNCSCI) was assessed at discharge and at 1-yr follow-up.

**Outcome Measures:** ISNCSCI motor score; Spinal cord independence measure III (SCIM); Radial diffusivity (RD); axial diffusivity (AD);

1. FA was significantly lower in SCI when compared to lower (p<0.001), mid (p<0.001), and upper (p<0.001) regions in healthy controls.
2. AD was significantly lower in SCI when compared to lower (p<0.001), mid (p<0.001), and upper (p<0.001) regions in healthy controls.
3. RD was significantly higher in SCI when compared to mid (p<0.001) and upper (p<0.001) regions of healthy controls. There was no significant difference in RD when comparing SCI to the lower region of healthy control (p=0.05).
4. There was no significant difference in MD when comparing SCI to all regions of healthy controls (p>0.05).
5. Pearson correlations revealed significant correlations between MD and the presence of hemorrhagic contusions (r=0.42, p<0.05), ISNCSCI motor score (r=0.66, p<0.05), and SCIM (r=0.64, p<0.05).
6. There was a significant correlation between FA and age (r=-0.55, p<0.05).
7. AD was significantly correlated with presence of hemorrhagic contusion (r=0.42, p<0.05), ISNCSCI motor score (r=0.76, p<0.001), and SCIM (r=0.77, p<0.01).
8. RD was significantly correlated with age (r=0.5, p<0.05) and ISNCSCI motor score (r=0.53, p<0.05).
9. Step-wise regression revealed MD (r$^2$=0.89, p=0.002), AD (r$^2$=0.93, p<0.001), and RD (r$^2$=0.86, p=0.014) were significant predictors of ISNCSCI motor score at the 1-

1. ADC was significantly lower in the SCI group in the upper (p=0.013), mid (p<0.001), and lower (p<0.001) regions when compared to healthy controls.
2. There were no significant differences in FA when comparing SCI to healthy controls at all three regions (p>0.05).
3. SCI showed significantly lower RA in the mid region when compared to healthy controls (p=0.037). There was no significant difference in RA for the upper and lower regions (p>0.05).
4. There were no significant differences in VR when comparing SCI to healthy controls at all three regions (p>0.05).
5. Whole cord Diffusion Tensor Imaging parameters showed significantly lower ADC and RA in participants with SCI (p<0.001; p=0.022, respectively).
6. Whole cord ADC, FA, and RA were significantly lower in SCI with hemorrhage compared to controls (p<0.001; p=0.0037; p<0.001). 

**Population**: SCI (n=20): Mean age=45.7±17.7yr; Gender: males=18, females=2; Level of injury: C=20; Time since injury=2hr-15d; The International Standard of Neurological Classification for SCI at discharge: A=5, B=2, C=3, D=6. Healthy Controls (n=8): Mean age=34.2±10.7yr; Gender: males=6, females=2. 

**Intervention**: All participants underwent Diffusion Tensor Imaging (DTI) with a 1.5T Avanto scanner with a 12-channel head and four-channel neck array using an echo-planar imaging (EPI) sequence at a repetition time/echo time (TR/TE) =8000/76ms and a resolution of 128X128 over a 20cm field of view (FOV). Images included sagittal T2 (TR/TE=4000/109ms), fluid-attenuated inversion recovery (TE/TR/echo train=8000/102ms/13), and axial T2 and T2* images. Regions of interest included upper (lower brainstem-lower C2), mid (upper C3-lower C5), and lower (upper C6-lower T1) regions. Medical records were reviewed to determine the extent of neurological deficit (e.g., quadriplegia, paraplegia).

**Discussion**

Studies have showed that the diagnostic value/psychometrics of different DTI measures such as apparent diffusion coefficient, fractional anisotropy, radial diffusivity, axial diffusivity, mean diffusivity, relative anisotropy, and volume ratio are highly statistically significant. In 2005, Facon et al., (2005) found that there was a statistically significant difference in the fractional anisotropy values between healthy controls and those with SCI groups. In particular, fractional anisotropy had a much higher sensitivity (SE=73.3%) and specificity (SP=100%) in spinal cord abnormalities detection compared with T2-weighted FSE imaging (SE=46.7%, SP=100%) and ADC (SE=13.4%, SP=80%). Koskinen et al., (2013) reveal that DTI revealed SCI pathology, which was undetectable using conventional MRI. Numerous studies including those by Choe et al., D’Souza et al., (2017), Shanmuganathan et al., (2008), Shanmuganathan et al., (2017), Kim et al., (2015), Koskinen et al., (2013) demonstrate a statistical difference in fractional anisotropy, axial diffusivity, radial diffusivity, apparent diffusion coefficient, relative anisotropy, and volume ratio values between healthy controls and those with SCI. Shanmuganathan et al., (2008) demonstrates that whole cord relative anisotropy, fractional anisotropy, and relative anisotropy were significantly lower in SCI with hemorrhage compared to controls, while volume ratio was significantly higher. Interestingly, they note that there was no significant differences in fractional anomalies.
anistrophy when comparing SCI to healthy controls. Overall, DTI parameters show considerable diagnostic value, in particular, in its high sensitivity and specificity and in detecting pathology not seen on MRI.

The evidence behind using DTI as a prognostication tool is mixed. Various studies have examined different DTI measures such as apparent diffusion coefficient, fractional anisotropy, radial diffusivity, axial diffusivity, mean diffusivity and their relationships with a number of functional and injury classification scores including International Standards for Neurological Classification of SCI, Functional Independence Measure, Spinal cord independence measure III, Frankel grading system score, American Spinal Injury Association motor score, modified Barthel index score and Abbreviated Injury Scale. Fractional anisotropy has shown promise as a prognostication tool.

In a 2013 case control study by (Koskinen et al.) the fractional anistrophy values in the SCI group were positively correlated with the motor and sensory scores of The International Standard of Neurological Classification for SCI. Moreover, the fractional anistrophy values in the same group were positively correlated with the motor subscale of Functional Independence Measure.

In 2017, (D’Souza et al.) found that there was a statistically significant positive correlation between fractional anistropy values at the level of injury and Frankel grading system score. In contrast, there was no significant correlation between mean diffusivity at the level of injury and Frankel grading system score.

Shanmuganathan et al., (2017) demonstrate that axial diffusivity was significantly correlated with presence of hemorrhagic contusion, The International Standard of Neurological Classification for SCI, and spinal cord independence measure III. Mean diffusivity, axial diffusivity, and radial diffusivity were significant predictors of The International Standard of Neurological Classification for SCI motor score at the 1-year follow-up for participants with or without hemorrhage spinal cord injury. However, fractional anisotropy was not a significant predictor in the model. Moreover, mean diffusivity, axial diffusivity, fractional anisotropy, and radial diffusivity were not significant predictors of spinal cord independence measure III at 1-year follow-up for both hemorrhagic and non-hemorrhagic spinal cord injury.

Meanwhile, Choe et al., found that there were no significant relationships between DTI indices and total International Standard of Neurological Classification for SCI scores from different spinal cord columns.

Conclusion

*There is level 3 evidence (from one case control study; Choe et al., 2017) that there may be no significant relationship between DTI incidences and total International Standard of Neurological Classification for SCI scores either at baseline or follow-up in individuals with SCI.*

*There is level 3 evidence (from one case control study; (D’Souza et al., 2017) that there may be a significant positive relationship between fractional anisotropy and Frankel grading system scores, but no relationship between mean diffusivity and Frankel grading system scores.*
There is level 3 evidence (from seven case control studies; Choe et al., 2017, (D'Souza et al., 2017, Ellingson et al., 2008a, Facon et al., 2005, Kim et al., 2015, Shanmuganathan et al., 2008, Shanmuganathan et al., 2017) that DTI may be an effective tool to measure microstructure abnormalities in individuals with an SCI compared to healthy controls.

There is level 3 evidence (from one case control study; (Shanmuganathan et al., 2017) that axial diffusivity may be positively correlated with the presence of hemorrhagic contusion, International Standard of Neurological Classification for SCI motor scores, and spinal cord independence measure III at both baseline and follow-up.

There is level 3 evidence (from one case control study; (Shanmuganathan et al., 2017) that axial diffusivity, radial diffusivity, and mean diffusivity may be a significant predictor of International Standard of Neurological Classification for SCI motor scores, but not spinal cord independence measure III scores, for both individuals with and without SCI.

There is conflicting level 3 evidence against (from one case control study; (Ellingson et al., 2008a), and one observational study; (Wang et al., 2016) and level 3 evidence for (from one case control study; (Koskinen et al., 2013) that DTI grading may have prognostic value in determining motor and sensory scores in individuals with SCI.

DTI has value as a diagnostic imaging tool to evaluate microstructural and spinal cord abnormalities in individuals with SCI.

There is conflicting evidence as to which observations from DTI can be used to predict current and future outcomes.

DTI may be effective for predicting relationships between different SCI abnormalities within individuals.
7.0 Summary

There is level 4 evidence (from one case series study; (Karpova et al., 2013), and two observational studies; (Ghasemi et al., 2015, Yasin et al., 2017) that MRI has strong inter-observer correlation, sensitivity, specificity, predictive value, and diagnostic accuracy in detecting and evaluating SCI in individuals.

There is level 5 evidence (from one case series study; (Schroeder et al., 2016) that the incidence of surgical treatment and spinal decompression is not significantly different between individuals based on the presence of signal intensity on an MRI.

There is conflicting level 3 evidence (from one cohort study; (Mabray et al., 2016), one case control study; (Seif et al., 2018), two case series; (Flanders et al., 1996), (Wilson et al., 2012), and six observational studies; (Aarabi et al., 2017, Schaefer et al., 1992, Selden et al., 1999, Song et al., 2016, Takahashi et al., 1993, Zohrabian et al., 2016) and level 5 evidence (from one observational study (Wang et al., 2016) that MRI is effective in determining microstructural measurements and can reliably predict AIS classification, motor score and status and progression of injury in individuals with SCI and controls.

There is level 5 evidence (from one cohort study; (Martinez-Perez et al., 2017) that early MRI has prognostic value in its ability to evaluate ligamentous injury and edema which are predictors of poor neurologic outcome.

There is level 5 evidence (from one observational study; (Miyanji et al., 2007) that MRI can be used to detect hemorrhage, edema, and cord swelling in individuals with SCI. A greater number of positive detections were significantly associated with increased SCI severity and American Spinal Injury Association classification.

There is level 5 evidence (from two observational studies; (Boldin et al., 2006; Shepard & Bracken 1999) that MRI may be used to predict complete SCI given the detection of hemorrhage and edema in individuals with SCI.

There is level 5 evidence (from one observational study; (Dalkilic et al., 2018) that MRI could be used to assess hematoma length and predict AIS classification at baseline.

There is level 5 evidence (from one observational study; (Matsushita et al., 2017) that MRI is effective in detecting spinal microstructures which can be used to effectively predict American Spinal Injury Association motor scores, and Frankel D scores in individuals with SCI.

There is level 5 evidence (Martinez-Perez et al., 2017) that an early MRI may have prognostic value in individuals with SCI without CT evidence of trauma.

There is level 5 evidence (from an observational study (Ouchida et al., 2016) that MRI may not be an effective diagnostic or prognostic indicator of injury in individuals diagnosed with SCI without radiographic abnormality.

There is level 3 evidence (from one case control study; Choe et al., 2017) that there may be no significant relationship between DTI incidences and total International Standard of Neurological Classification for SCI scores either at baseline or follow-up in individuals with SCI.
There is level 3 evidence (from one case control study; (D’Souza et al., 2017) that there may be a significant positive relationship between fractional anisotropy and Frankel grading system scores, but no relationship between mean diffusivity and Frankel grading system scores.

There is level 3 evidence (from seven case control studies; Choe et al., 2017, (D’Souza et al., 2017, Ellingson et al., 2008a, Facon et al., 2005, Kim et al., 2015, Shanmuganathan et al., 2008, Shanmuganathan et al., 2017) that DTI may be an effective tool to measure microstructure abnormalities in individuals with an SCI compared to healthy controls.

There is level 3 evidence (from one case control study; (Shanmuganathan et al., 2017) that axial diffusivity may be positively correlated with the presence of hemorrhagic contusion, International Standard of Neurological Classification for SCI motor scores, and spinal cord independence measure III at both baseline and follow-up.

There is level 3 evidence (from one case control study; (Shanmuganathan et al., 2017) that axial diffusivity, radial diffusivity, and mean diffusivity may be a significant predictor of International Standard of Neurological Classification for SCI motor scores, but not spinal cord independence measure III scores, for both individuals with and without SCI.

There is conflicting level 3 evidence against (from one case control study; (Ellingson et al., 2008a), and one observational study; (Wang et al., 2016) and level 3 evidence for (from one case control study; (Koskinen et al., 2013) that DTI grading may have prognostic value in determining motor and sensory scores in individuals with SCI.
